ABSTRACT

We present a multiwavelength study of GRB 060108 – the 100th gamma-ray burst discovered by Swift. The X-ray flux and light curve (three segments plus a flare) detected with the X-ray Telescope are typical of Swift long bursts.

We report the discovery of a faint optical afterglow detected in deep $BVRi'$-band imaging obtained with the Faulkes Telescope North beginning 2.75 min after the burst. The afterglow is below the detection limit of the Ultraviolet/Optical Telescope within 100 s of the burst, while evident in $K$-band images taken with the United Kingdom Infrared Telescope 45 min after the burst. The optical light curve is sparsely sampled. Observations taken in the $R$ and $i'$ bands can be fitted either with a single power-law decay in flux, \( F(t) \propto t^{-\alpha} \) where \( \alpha = 0.43 \pm 0.08 \), or with a two-segment light curve with an initial steep decay \( \alpha_1 < 0.88 \pm 0.2 \), flattening to a slope \( \alpha_2 \sim 0.31 \pm 0.12 \). A marginal evidence for rebrightening is seen in the $i'$ band.

Deep $R$-band imaging obtained \( \sim 12 \) d post-burst with the Very Large Telescope reveals a faint, extended object (\( R \sim 23.5 \) mag) at the location of the afterglow. The optical light curve had a break before 12 d, akin to what observed in the X-rays.

We derive the maximum photometric redshift \( z < 3.2 \) for GRB 060108. We find that the spectral energy distribution at 1000 s after the burst, from the optical to the X-ray range, is best fitted by a simple power law, \( F_{\nu} \propto \nu^{-\beta} \), with \( \beta_{OX} = 0.54 \) and a small amount of extinction. The optical to X-ray spectral index \( (\beta_{OX}) \) confirms GRB 060108 to be one of the optically darkest bursts detected. Our observations rule out a high redshift as the reason for the optical faintness of GRB 060108. We conclude that a more likely explanation is a combination of an

intrinsic optical faintness of the burst, a hard optical to X-ray spectrum and a moderate amount of extinction in the host galaxy.

**Key words:** gamma-rays: bursts.

## 1 INTRODUCTION

Gamma-ray bursts (GRBs) are brief, intense and totally unpredictable flashes of gamma-rays on the sky that are thought to be produced either during the core collapse of massive stars (long-duration bursts) or during the merger of two compact objects, such as two neutron stars or a neutron star and stellar mass black hole. Until the recent launch of the *Swift* satellite in 2004 November, it was notoriously difficult to observe GRBs at other wavelengths within seconds or minutes after the burst. Nevertheless, the successful identification with *BeppoSAX* of bright, long-lived X-ray afterglow emission for long bursts (Costa et al. 1997) and that of the corresponding optical and infrared (IR) counterparts (van Paradijs 1997), established GRBs as cosmological, and therefore the most instantaneously luminous objects in the Universe. Similar break-throughs for short bursts have recently occurred, showing them also to be extragalactic, but less luminous and less distant than long bursts (Barthelmy et al. 2005; Fox et al. 2005; Gehrels et al. 2005; Villasenor et al. 2005; Covino et al. 2006).

With the availability of *Swift’s* promptly disseminated arcsec localizations and the onboard rapid-slew X-ray Telescope and Ultraviolet/Optical Telescope (XRT and UVOT, respectively; Gehrels et al. 2004), multiwavelength monitoring of GRBs from the earliest possible times is now being performed for a significant number of bursts. Additionally, large-aperture ground-based robotic telescopes, such as the 2-m Liverpool (Steele 2004) and Faulkes telescopes, respond rapidly to GRB alerts and begin automatically imaging the target field within minutes of the receipt of an alert, providing early deep upper limits or multicolour follow-ups of optical counterparts as faint as $R \sim 18–22$ mag (e.g. Guidorzi et al. 2005, 2006b; Monfardini et al. 2006a).

Despite increasingly rapid responses that provide sensitive limits within minutes of the burst, the absence of long-wavelength emission afterglows for a significant number of GRBs (so-called ‘dark bursts’) remains a key unsolved problem. In the pre-*Swift* era, as many as 50 per cent of *BeppoSAX* bursts were lacking an optical detection (Lazzati, Covino & Ghisellini 2002; De Pasquale et al. 2003). The discovery rate of optical afterglows was even higher for HETE2 than for *SAX* (Lamb et al. 2004), and it was expected to increase significantly in the *Swift* era of rapid follow-up. Instead, a substantial fraction of *Swift* bursts remain undetected in the optical band (Roming et al. 2006). Possible scenarios to explain the ‘observed’ optical darkness of these bursts, apart from fast-fading transients lacking sufficiently deep, early-time observations (Groot et al. 1998), include intrinsically-faint optical afterglows (Fynbo et al. 2001; Lazzati et al. 2002; De Pasquale et al. 2003; Berger et al. 2005), highly obscured afterglows whose optical light is absorbed by the circumburst or interstellar material (Lazzati et al. 2002; De Pasquale et al. 2006), high redshifts (Fruchter 1999; Lamb & Reichart 2000; Berger et al. 2002; Bromm & Loeb 2002; Tagliaferri et al. 2005), and radiative suppression in a subclass of bursts with unusually high gamma-ray efficiency producing intrinsically low X-ray and optical fluxes (Pedersen et al. 2006; Roming et al. 2006).

Here, we present a multiwavelength X-ray, optical and IR study of the optically-faint GRB 060108. The Burst Alert Telescope (BAT, Barthelmy et al. 2005) was triggered by this GRB — *Swift*’s 100th burst — at 14:39:11.76 UT on 2006 January 8. The gamma-ray light curve has a single peaked structure with a FRED time profile (Oates et al. 2006), a duration $T_{90} = 14.4 \pm 1.6$ s (in the 15–350 keV band), and a 15–150 keV fluence $S_e = (3.7 \pm 0.4) \times 10^{-7}$ erg cm$^{-2}$. Here and in the following, errors are at 90 per cent confidence level, unless specified otherwise. The *Swift* XRT and UVOT began observing at 91 and 76 s after the BAT trigger, respectively, followed shortly after by the Faulkes Telescope North (FTN) at 2.75 min post-trigger. IR observations with the UKIRT were acquired during the optical imaging period beginning at 45 min post-burst. The VLT was used to obtain further near-infrared (NIR) imaging at 16.1 h and 2.7 d. Following an initial estimate of the position of the X-ray afterglow (Page et al. 2006), a revised location was derived (Butler & Bloom 2006); the location of the optical (Monfardini et al. 2006a) and IR counterparts (D’Avanzo et al. 2006; Levan et al. 2006a) was found to be consistent with this revised XRT position. Deep $R$-band imaging and spectroscopy were subsequently performed with the VLT at 12.7 and $\sim 21$ d, respectively.

## 2 OBSERVATIONS AND ANALYSIS

### 2.1 Swift gamma-ray observations

At 14:39:11.76 UT, on 2006 January 8, the *Swift* BAT triggered and located GRB 060108 (BAT trigger 176453) (Oates et al. 2006). Unless otherwise specified, times in this section are referenced to the BAT trigger time, hereafter designated $T_0$. The burst was detected in the fully coded part of the BAT field of view, meaning that all BAT detectors were illuminated by the source. The spacecraft began to slew to the source location 11.2 s after the trigger and was settled at the source location at $T_0 + 73.20$ s.

The BAT data for GRB 060108 between $T_0 - 300$ and $T_0 + 300$ s were collected in event mode with 100-μs time-resolution and 6-keV energy resolution. The data were processed using standard *Swift*-BAT analysis tools and the spectra were fitted using XSPEC v11.3. Before processing, the BAT event data were corrected for mask tagged weighting using the standard BAT tool, BATMASKWTREV. This procedure scales each count in each detector by an amount proportional to the portion of the detector exposed to the source through the empty spaces in the BAT coded mask. The mask weighting effectively removes the background, and all BAT light curves in this paper have been background subtracted by this method.

### 2.2 Swift X-ray observations

The XRT (Burrows et al. 2005a) position refined analysis located this burst at $\alpha(J2000) = 09^h48^m01^s6, \delta(J2000) = 31^\circ 55'04''6$ (Page et al. 2006). The XRT began observations approximately 90 s after the burst trigger. The analysis of the XRT data was performed using the XRT pipeline software version 2.3. The initial exposure was taken in Image Mode and no source was detected. The XRT...
then observed in Windowed Timing (WT) mode for \(\sim10\) s before switching to Photon Counting (PC) mode for a further 10 ks; a fading uncatalogued source was detected. Swift observed the field until 100 s after the burst trigger.

The source and background counts used to create the light curve and the spectra were obtained from the cleaned event files using extraction regions. The analysis of the WT mode data provided only limited results as the exposure was of such a short duration.

The first 1000 s of PC data were found to be piled up. The size of the region that was affected by the pile-up was determined by comparing the measured point spread function (PSF) with a model XRT PSF. The affected radius was found to be 1.6 pixels (4 arcsec) in radius; therefore, an annular region with inner radius 4 arcsec and outer radius of 30 pixels (70.8 arcsec) has been used for the extraction. The rest of the PC data were extracted using a circular region of radius 30 pixels (70.8 arcsec) and a background region of radius 80 pixels (189 arcsec). These regions were used to extract data from all orbits of PC data.

When extracting the PC-mode spectrum, only events with grade 0–12 were used, and for the WT mode, events were used of grade 0–2. The energy response of the detector was taken into account in radius; therefore, an annular region with inner radius 4 arcsec and outer radius of 30 pixels (70.8 arcsec) has been used for the extraction. The rest of the PC data were extracted using a circular region of radius 30 pixels (70.8 arcsec) and a background region of radius 80 pixels (189 arcsec). These regions were used to extract data from all orbits of PC data.

2.3 Optical and NIR imaging

2.3.1 Swift Ultraviolet Optical Telescope

The UVOT began observations 75 s after the BAT trigger. The first \(\sim11\) s exposure, taken while the spacecraft was settling on the target, was taken through the V filter in photon-counting (‘Event’) mode. Once the pointing had stabilized, a 200-s V-band finding-chart exposure in Image/Event mode was taken. After this, the UVOT cycled through the colour filters. The later exposures were in image mode only. Counts were extracted from the images using a 3-arcsec-radius aperture at the position of the optical afterglow given in this paper. The count rates were aperture-corrected to ensure compatibility with the photometry calibration by Poole et al. \(^1\). We then derived the 3\(\sigma\) upper limits in count units, which were converted to magnitudes using the zero-points available in the Swift CALDB, and corrected for Galactic extinction using \(E(B-V) = 0.018\). Results are given in Table 1.

2.3.2 Faulkes Telescope North

The FTN, located on Maui, Hawaii, responded robotically to the Swift alert and began observing 2.75 min after the GRB trigger. The initial detection mode images (three 10-s R-band exposures) were processed automatically by the Liverpool GRB pipeline, LT-TRAP (Guidorzi et al. 2006a). No new source has been identified in the XRT error box (Page et al. 2006) brighter than \(R \sim 19.5\) mag (\(\Delta t = 3.1\) min) and \(R \sim 20.2\) mag (\(\Delta t = 11.7\) min) in comparison with USNO-B1.0, Two-Micron All-Sky Survey (2MASS) and GSC 2.3 catalogues (Guidorzi et al. 2006b). The telescope continued in multicolour imaging mode, obtaining the exposures in \(BVRi\) bands.

The robotic follow-up ended after one hour. A subsequent post-processing of the \(i\)-band images revealed an uncatalogued source \(\sim3\) arcsec north-east of the edge of the XRT error circle (see Fig. 1). The \(i\)-band brightness of this source in the FTN image relative to the neighbouring object was greater than in the pre-burst Sloan Digital Sky Survey (SDSS) \(i\)-band image, suggesting it as the candidate afterglow. Subsequent analysis of the XRT data by Butler & Bloom (2006) confirmed an XRT offset with a revised position for the afterglow \(\alpha(J2000) = 09^h48^m01^s92, \delta(J2000) = 31^\circ55'07''.8\) with 0\% uncertainty (90 per cent containment). As can be seen in Fig. 1, the location of the optical afterglow at \(\alpha(J2000) = 09^h48^m01^s98, \delta(J2000) = 31^\circ55'08''.6\) with \(\sim0.5\) uncertainty

*4Marginal detection with low statistical significance. Errors are derived by adding statistical and systematic errors in quadrature. Magnitudes are uncorrected for Galactic extinction. $3σ$ upper limits are quoted for non-detections. Column 7 lists the time range covered by the exposures and column 8 lists the corresponding exposure-weighted mean time ($Δt$), since the burst for co-added images is calculated as $Δt = \sum t_i Δt_i / \sum \Delta t_i$.*

**Table 3.** GRB 060108: VLT observation log. Errors are at 90 per cent confidence level, while $3σ$ upper limits have been used for the non-detection.

(90 per cent containment, Monfardini et al. 2006a), is consistent with the revised XRT position. A similar location is derived for the NIR counterpart identified by D’Avanzo et al. (2006) and Levan et al. (2006a). A careful analysis of the optical data subsequently confirmed that the source was fading, and further imaging with the FTN and other telescopes was manually triggered to follow the later-time evolution. Unfortunately, moon and weather constraints prevented deep detections or limits beyond $R < 23$ mag. Table 2 summarizes the results of the optical and NIR imaging; as no FTN observations of standard stars were available, magnitudes in $B$, $V$, $R$, and $i'$ were calibrated as follows. Observations in $i'$ band were calibrated directly using the SDSS DR4 photometry,2 while $B_i$, $V_i$, and $R$-band data were calibrated assuming the pre-burst SDSS $g'$/$i'$ photometry of Cool et al. (2006a,b) combined with observed filter transformations given by Smith et al. (2002) in their Table 7. Finally, the data were corrected for the Galactic extinction, which is low towards GRB 060108: $A_B = 0.09$ mag, $A_V = 0.07$ mag, $A_R = 0.05$ mag, $A_i = 0.04$ mag (Cardelli et al. 1989; Schlegel et al. 1998). Magnitudes were converted into flux densities ($\mu $Jy) following Bessel (1979) and Fukugita et al. (1996) for comparison with X-ray flux densities.

2.3.3 Very Large Telescope (VLT)

$J$- and $K_s$-band observations of the field of GRB 060108 were performed by using the ISAAC camera at two different epochs, and in the $R$ band by using the FORS 1 instrument at one epoch (see Table 3). Both instruments are mounted on the ESO-VLT located at Cerro Paranal (Chile). All nights were photometric, with a seeing in the range 0.8–1.4 arcsec. An image reduction was performed following the standard procedures. Astrometric solutions were computed using the USNO catalogue.3 An aperture photometry was performed using $\text{SEXTRACTOR}$ (Bertin & Arnouts 1996). In the optical, the flux calibration was performed observing Landolt standard stars. In the NIR, the 2MASS catalogue (Skrutskie et al. 2006) was adopted as a reference, even if only a handful of usable stars were present in the ISAAC field. Late-time low-resolution spectra were acquired with the VLT in an attempt to measure the host galaxy redshift. However, the object was quite faint and spectra have a very low signal-to-noise ratio ($S/N$), with no clear emission or absorption lines. We will not discuss further these spectra.

In Table 3, we present the observing log and list the results of our spectrophotometric analysis for each epoch.

3 RESULTS

3.1 GRB 060108 and its afterglow

The afterglow of GRB 060108 is detected at X-ray (Page et al. 2006), optical (Monfardini et al. 2006a) and NIR wavelengths (Levan et al. 2006a). The X-ray light curve shows the canonical three-segment decay similar to many GRBs detected with $\text{Swift}$, with a small flare

2 www.sdss.org/dr4/.

300 s after the burst. Optically, the burst is not detected at ultraviolet (UV) and optical wavelengths with the UVOT in the first two minutes, but it is detected in deeper B-, V-, R- and i-band FTN images as early as 5.3 min after the burst. The optical afterglow of GRB 060108 is one of the faintest yet discovered.

### 3.2 Swift gamma-ray light curve and spectra

The BAT light curve (see Fig. 2) shows a simple triangular profile in all energy bands, with a rise from background starting at \( T_0 - 4.0 \) s, a peak at \( T_0 \), and a return to background levels by \( T_0 + 13.2 \) s. A small secondary peak is seen at around \( T_0 + 10 \) s, but then no detectable emission has been registered either after \( T_0 + 13.2 \) s or at the times of the flare seen by the XRT. The peak count rate measured by BAT is 2000 counts s\(^{-1}\) at \( T_0 \), and the duration is \( T_{90} = 14.4 \pm 1.6 \) s (15–350 keV band; estimated error including systematics). The 1-s peak photon flux measured from \( T_0 - 0.48 \) s is 0.7 ± 0.1 photons cm\(^{-2}\) s\(^{-1}\) (in the 15–150 keV band).

For the spectral analysis, we have analysed the data between 15 and 150 keV, where BAT has a better response. We find that the emission from GRB 060108 shows the hard to soft spectral evolution commonly observed in many GRBs and that, for all time periods, the best fit to the BAT data is a simple power law. The spectrum of the first peak (\( T_0 - 4.02 \) to \( T_0 + 9 \) s) is best fitted with a photon index of 1.9 ± 0.17 (\( \chi^2/d.o.f. = 54/90 \)), while that of the smaller second peak (\( T_0 + 9 \) to \( T_0 + 13.2 \) s) has a photon index 2.55 ± 0.61 (\( \chi^2/d.o.f. = 64/90 \)). With the given spectral parameters, this burst appears to share some similarity with the X-ray flashes (XRFs).

Although \textit{Swift} is not well suited to identify XRFs, since it lacks coverage at low energy (i.e. in the ‘classical’ HETE band 2–30 keV), we note that, if the spectrum is extrapolated down to this band, then the soft photon index would imply either an XRF or at least an X-ray rich event.

### 3.3 Swift X-ray light curve and spectra

By following O’Brien et al. (2006), the BAT light curve can be extrapolated at lower energies and joined to the XRT light curve in a single plot. Although some consideration is needed (as the energy bands of the two instruments do not overlap), this is a powerful method which allows us to visualize the decay rate of the event through a longer time interval, commencing at the burst trigger. The combined BAT and XRT light curve resulting from this process is shown in Fig. 3. For the extrapolation, we used a BAT photon index of 1.9 (computed in the 15–150 keV band).

The light curve has a complex shape, showing a steep decay, followed by a flatter phase which eventually steepens again. A visual inspection shows a possible flare, superimposed between the two segments. We modelled the X-ray light curve with both a double broken power law and a double broken power law with the inclusion of a Gaussian, to represent the flare. In the first case, we find a \( \chi^2/d.o.f. = 26/23 \), whereas using the second model gives \( \chi^2/d.o.f. = 11/20 \). The probability that this improvement is due to chance, calculated using the F-test, is 0.05 per cent. In order to check for overfitting effects, we repeated the fitting by adopting different choices for the temporal binning. We find that, in all cases, the light curve is better fitted by including a Gaussian, although in some cases both fits (with and without Gaussian) have reduced \( \chi^2 \) values larger than unit, and in turn the decrease in \( \chi^2 \) is less pronounced. The probability that the improvement is due to chance, calculated using the F-test, varies between 0.019 and 0.035 in the different fits, which means that the fit including the Gaussian can be used with a confidence of \( \gtrsim 2\sigma \). The best-fitting parameters appear to be always consistent with each other, and are given in Table 4; here and in the following, we assume the convention \( F \propto t^{\alpha} \nu^{\beta} \). Are we happy with this or is better to present one of the first with both \( \chi^2 > 1 \) and change all little numbers in the discussion?

Our analysis shows that there are three distinct segments in the X-ray light curve. The X-ray afterglow starts with a phase of steep decay.
Table 4. Best-fitting parameters for a fit of the XRT light curve of GRB 060108 with a double broken power-law model plus a Gaussian. The epoch of the flare, $t_{\text{flare}}$, and its width, $\sigma_G$, have been reported. From the Gaussian component, the full-width at half-maximum (FWHM) is related to $\sigma_G$ by FWHM = $2.35\sigma_G$. Errors are at 90 per cent confidence level.

Table 5. X-ray spectral indices for GRB 060108. Errors are at 90 per cent confidence level. When possible, we report the 90 per cent upper limit on the excess in column density, over the Galactic value of $N_H^{\text{Gal}} = 1.7 \times 10^{20}$ cm$^{-2}$ (Dickey & Lockman 1990). The energy indices of the first and second segments have been computed twice: with ($\beta_i$) and without ($\beta'_i$) the inclusion of the X-ray flare. In the second case, Cash statistics have been used.

decay (first segment, slope $\sim 2.8$), followed by a shallow section (second segment, slope $\sim 0.3$), and finally enters a ‘normal afterglow’ decay phase, with a slope $\sim 1$ (third segment). The two break times which separate these three segments are $t_{\text{break,1}} \sim 250$ s and $t_{\text{break,2}} \sim 11.5$ ks. This behaviour is typical of X-ray afterglow light curves as shown by Nousek et al. (2006).

In order to perform a spectral analysis, we fitted the spectra taken during different time intervals by using an absorbed power-law model. The Galactic value of the column density has been fixed at $N_H^{\text{Gal}} = 1.7 \times 10^{20}$ cm$^{-2}$ (Dickey & Lockman 1990); this value is in agreement with that obtained from the more recent Leiden/Argentine/Bonn Galactic H I Survey (LAB Survey), which is $1.8 \times 10^{20}$ cm$^{-2}$, Kalberla et al. (2005), and an additional absorption component, $N_L$, has been allowed to mimic the intrinsic excess in column density. Results are summarized in Table 5.

The spectral indices before and after the first break at $250 \pm 30$ s have been first computed by including the flare at $300 \pm 10$ s ($\beta_i$ in the table). In the attempt to assess the flare contamination on these values, we divided the interval into three parts by isolating the time interval of the flare. Since these new spectra contained less than 100 background-subtracted counts, Cash statistics were used for the fitting (a minimum of 15–20 counts per bin are required for Gaussian $\chi^2$ statistics). A comparison of the resulting indices, $\beta'_i$, with the $\beta_i$ previously computed, shows that the flare does not alter significantly the spectral indices registered during the first two decay phases.

Because of the low statistics, when considering the spectra of individual segments separately, we are unable to constrain the value of the excess of column density over $N_H^{\text{Gal}}$. We have only been able to derive a 90 per cent upper limit, and only by using the spectra of the last two time intervals. In order to have an estimate for the photoelectric absorption, we re-extracted the X-ray spectrum using all data after the flare through to the end of the observations (time interval $570 < t < 4.63 \times 10^2$ s). Since this spectrum has a better S/N, the excess $N_H$ is actually significant at 99 per cent confidence level; the best-fitting spectral parameters are $\beta_i = 1.06^{+0.27}_{-0.23}$, $N_H = 1.03^{+0.75}_{-0.66} \times 10^{21}$ cm$^{-2}$ (see also Section 4.2).

### 3.4 Optical and IR properties

The optical and IR properties of the GRB 060108 afterglow are also particularly interesting. Fig. 1 shows the identification of the optical afterglow with the X-ray counterpart in an FTN $i'$-band image, whereas Fig. 4 shows the optical and IR light curves, including detections and upper limits from optical to NIR wavelengths, corrected for Galactic extinction. As shown in Table 2, the afterglow is visible in all $BVRi'$ bands from as early as $\Delta t \sim 5$ min, but is not detected by the UVOT within the first few minutes of the trigger or during the short-exposure FTN $R$- and $B$-band images taken at 164 and 274 s after the trigger, respectively. Although these FTN exposures have only a $\sim 10$ s duration, the deep limits rule out a significant optical flare coincident in time with that possibly seen in the X-ray light curve. Moreover, the marginal FTN $V$-band detection (Table 2 and Fig. 4) reveals that the afterglow was already fainter than the UVOT limiting magnitudes.

The optical light curves to 4000 s after the burst can be fitted with a single power-law decay in flux density $F(t) \propto t^{-\alpha}$, where $\alpha = 0.43 \pm 0.08$ (Fig. 5), a slope that is also consistent with the gradient between the two $K$-band detections. Alternatively, guided by the structure in the X-ray light curve and concentrating on the $R$- and $i'$-band light curves, a more complicated interpretation is possible. By a direct comparison between the X-ray and optical flux density evolution (see Fig. 4), we find that, although the optical light curves are sparsely sampled (due to the need to co-add frames), there is evidence for a two-segment light curve. A possible rebrightening is

---

seen in i′ band, although the significance is low and a monotonic decay is not ruled out. Using the early time R-band upper limit as a constraint on the maximum possible value of α and fitting the R-band light curve in two time portions 300 < t_1 < 1000 s and t_2 > 800 s, we derive α_1 < 0.88 ± 0.2 and α_2 = 0.31 ± 0.12. The second decay α_2 is found to be shallow whether or not the late-time VLT R-band measurement at 12.68 d is included and, by assuming that a break has not occurred in the optical light curve, this may represent a faint detection of the afterglow. On the other hand, as suggested by the X-ray light curve, it is possible that a break has already occurred around t_{break,2} ∼ 11.5 ks, in which case the predicted magnitude of the optical counterpart would be significantly fainter than R ∼ 23.5 mag at 12.68 d. As discussed in Section 4, if taken at face value the apparent rebrightening in the i′-band light curve (Fig. 4) may be interpreted as due to a further emission mechanism (possibly a second reverse shock). In such a case, the decay at the end of the first hour may be significantly steeper than α_2 ∼ 0.31, similar instead to α_1. Moreover, in the late VLT image the object is not point like but clearly extended, making likely that the emission detected at such late time is dominated by the host galaxy (at least ∼50 per cent of the total flux).

### 3.4.1 Photometric redshift derivation

In order to estimate the photometric redshift of GRB 060108, we adopted a χ² minimization of the observed optical to IR spectral energy distribution (SED) based on the technique presented by Fontana et al. (2000). This is a widely used and well-tested technique for redshift determination of galaxies (in which case it takes into account star formation history of each galaxy type and other effects; Fernandez-Soto et al. 1999; Csabai et al. 2000; Rowan-Robinson 2003; Melandri et al. 2006) which has been recently re-adapted to fit simple power-law SEDs, as those typical of GRB afterglows.

The photometric redshift was determined by combining contemporaneous optical and NIR flux measurements derived from the early-time FTN and UKIRT imaging at 45 min after the burst. The BRIK values were extrapolated to 3600 s using different values for the temporal decay index ranging from α = 0.3 to 0.6 (see Fig. 6). Following the method described in Melandri et al. (2006), the magnitudes were converted to the AB system before inputting them into the photometric redshift determination algorithm.

Adopting a χ² minimization of the observed SED (which is assumed to follow a power law F_ν ∝ ν^−β) at 3.6 ks after the trigger, we derive a maximum redshift of z < 3.2 at 90 per cent confidence level.

Moreover, by using the temporal decay value of α = 0.4 obtained by the simple power-law fit discussed in Section 3.4, the minimization returns β_0 = 1.42. The results obtained by using this value for α are shown in Fig. 6. Here the top panel shows the derived AB magnitudes, corresponding to BRIK values, and the best-fitting curve; the bottom panel shows the reduced χ² distribution as a function of photometric redshift. The χ² distribution does not show a minimum: it is very flat from z ∼ 0 to ∼2 and then starts increasing if z > 2.4. Therefore, it does only allow setting an upper limit determination for z.

The numerical technique used here does not account for intrinsic absorption. In the attempt to estimate this effect, we imposed a power law on the whole SED from the optical to X-ray wavelength.

range, and used a Small Magellanic Cloud (SMC) extinction profile. By taking $z \sim 2$, we find $A_v = 0.26^{+0.09}_{-0.11}$ and $\beta_{OX} = 0.54^{+0.23}_{-0.12}$. The shallower value of $\beta_{OX} = 0.54^{+0.23}_{-0.12}$ is preferable: if $\beta_{O}$ is as steep as $\sim 1.1$, we would be unable to account for the SED from optical to X-ray according to the synchrotron spectrum of the afterglow. Moreover, $\beta_{OX} = 0.54^{+0.23}_{-0.12}$ is fully consistent with the X-ray slope registered at the same time, as shown in Table 5.

4 DISCUSSION

4.1 Afterglow model

The X-ray afterglow of GRB 060108 is quite complex and exhibits several of the interesting features which have been recently observed in other GRBs by Swift (see Burrows et al. 2005b; Nousek et al. 2006; Roming et al. 2006; Zhang et al. 2006, for detailed discussions). In particular, in several cases the X-ray emission has been found to consist of an initial steep decay, followed by a shallow one about 100–1000 s after the trigger. A second change of the decay slope usually occurs about 10 ks later. Flares can be observed superimposed to this template behaviour, and they are usually thought to be produced by internal shocks that should occur during the prompt emission phase.

In the case of GRB 060108, we have registered three different spectral slopes. The X-ray light curve initially follows the standard pattern of rapid to shallow transition, and then, after $t_{\text{break,1}} \sim 11.5$ ks, the afterglow enters the ‘normal afterglow’ phase. Also, a small X-ray flare has been observed at $t \sim 300$ s.

According to the standard interpretation, the initial fast decay is likely to be associated with the tail of the prompt emission. In such a case, the relationship between the spectral and decay indices should be given by $\alpha = 2 + \beta$ (‘curvature relation’, see Kumar & Panaitescu 2000; Zhang et al. 2006). In the case of GRB 060108, it is $\alpha_1 = 2.78^{+0.43}_{-0.43}$ and $\beta_1 = 1.47^{+0.42}_{-0.42}$; therefore, the agreement is only marginal. The value of $\alpha$ required for the curvature relation to be satisfied is $\sim 3.5$, although the shallower initial slope observed in our case may possibly be caused by the presence of the flare at $\geq 300$ s. In fact, the $\alpha = 2 + \beta$ relation gives the steepest decay index for a spherical model and is expected to be satisfied only when emission from on-axis fluid elements is shut off suddenly, and off-axis emission dominates. The presence of minor internal shocks at later times would make the decay more gentle. On the other hand, Fig. 3 shows that the backward extrapolation of the XRT data well matches the flux level of the prompt emission, as registered by BAT and extrapolated in the XRT band, strengthening the idea that the initial fast decay of the X-ray emission is related to the prompt emission.

Just after the rapid decay phase, we observe a small flare that peaks at $300 \pm 10$ s and, when modelled with a Gaussian, has a width $\sigma_t = 32.3 \pm 10.0$ s. By adopting different rebinning for the X-ray light curve, we have found that the $\chi^2$ always shows an improvement by adding a Gaussian to the fitting model, and that the confidence level for the flare is $\sim 2 - 2.5 \sigma$. Such X-ray flares are common features of Swift XRT light curves (Liang et al. 2006; Zhang et al. 2006), and are usually associated with collisions between ultrarelativistic shells emitted by the ‘inner engine’ after the main high-energy event. In this case, the decay slope and the spectral index of the flare should again satisfy the curvature relation, at least provided that the decay slope is computed by re-setting the time-zero point $t_0$ at the start of the shell emission (see Zhang et al. 2006 and references therein). Although the flare statistic is quite low and does not allow a robust determination of the slope, we find that this relation is satisfied by taking $t_0 = 282$ s. This gives $\alpha_g = 4.7 \pm 1.1$ (90 per cent confidence level, while the spectral index is $\beta = 1.7 \pm 0.4$, see Table 5).

After $t_{\text{break,1}} = 250 \pm 30$ s, the GRB 060108 afterglow enters a phase of plateau, which we can attribute to the emission from the forward shock produced when the fireball runs into the circumburst medium (see O’Brien et al. 2006; Zhang et al. 2006). However, the observed temporal decay slope is shallower than that expected from a standard afterglow decline (Sari, Piran & Narayan 1998), requiring that additional energy is injected into the afterglow (‘refreshed’ afterglow). Three possible mechanisms have been proposed to explain this late energy injection (Zhang et al. 2006 and references therein). (i) A continuous activity from a longer lasting central engine, usually mimicked by a central engine luminosity law of the kind $L \propto t^{-q}$, (ii) a power-law distribution of the Lorentz factors in the ejecta, causing slower shells to catch up with the decelerated fireball, or (iii) the deceleration of highly magnetized ejecta, in which case the outflow is Poynting flux dominated and transfers energy to the medium. In the latter case, however, a good parametrization of the energy release is still lacking; therefore, we will not discuss this possibility in further details (see Zhang & Kobayashi 2005 and Zhang et al. 2006 for a discussion).

By using the closure relations listed by Zhang et al. (2006, see their table 2), we find that the relation which is satisfied by the spectral and decay indices during this phase ($\alpha \sim 0.3$ and $\beta \sim 0.7$, see Tables 4 and 5) is $\alpha = (q - 1) + (2 + q)\beta/2$, giving $q = 0.44$. All other possibilities are excluded. This implies that the fireball is propagating into a constant density medium, such as the interstellar medium (ISM), and that the X-ray frequency lies between the synchrotron frequency and the cooling frequency ($\nu_m < \nu < \nu_c$). During this epoch, the central engine does not turn off, but continues to inject energy in the outflow according to the law $L \propto t^{-0.44}$. This result makes unlikely that the late energy injection is due to electromagnetic emission from a highly magnetized and rapidly rotating pulsar (which, in principle, can be formed after the explosion of the supermassive star producing the GRB), as this would normally require a flatter injection rate during the initial spin-down phase ($q \sim 0$), followed by an asymptotic decay with $q \sim 2$ (see Zhang & Mészáros 2001). Similarly, any mechanism causing a nearly constant input of energy (e.g. early phases of disc accretion, during which the accretion rate, $\dot{M}$, can be nearly constant, etc.) can be ruled out. However, continued infall of matter on to a newly formed black hole may occur with $q < 1$, since at late times $\dot{M}$ is expected to fall off like a power law.

As mentioned before, an alternative and observationally indistinguishable scenario is one in which the central engine activity is brief, but the ejecta have a distribution of Lorentz factors. The fastest shells initiate the forward shock, decelerate, and are successively caught by the slowest shells producing internal shocks. The consequent addition of energy in the blast-wave mitigates the deceleration and the afterglow decay rate. Assuming a Lorentz factor distribution $M(\gamma) \propto \gamma^q$, where $\gamma$ is the shell Lorentz factor, the index $q$ is related to $\alpha$ by $s = -(10 - 7q)/(2 + q)$, which, in this case, gives $s = -2.83$.

The X-ray light curve breaks steeply at 11.5 ks. We can exclude that this is due to the passage of the cooling frequency through the X-ray band at this time, since in such a case, when comparing parameters relative to the epochs before and after the time break, we would expect to observe a relatively large change in the X-ray temporal slope of $\Delta \beta = 0.25$, accompanied by a similar change in the spectral slope of $\Delta \beta = 0.5$. In the case of GRB 060108, the observed change in the decay slope is $\Delta \alpha = 0.76 \pm 0.12$, while the spectral change is only $\Delta \beta = 0.03 \pm 0.27$ at 90 per cent confidence level.
level. This means that this interpretation is not compatible with the data (less than $\sim 3\sigma$).

More likely, the second break at $t_{\text{break,2}} = 11.5 \pm 0.4$ ks occurs when the additional energy injection ceases and the afterglow enters a ‘normal’ decay phase. During this phase, temporal and spectral indices satisfy the closure relation $\alpha = 3\beta/2$, which again confirms that the fireball is propagating in an ISM-like medium. This also requires the X-ray frequency to be below the cooling frequency during the entire duration of XRT observations. The corresponding index of the power-law energy distribution of radiating electrons is $p = 2.39$.

The comparison between the optical and X-ray light curve is also illuminating. Interestingly, the $i'$- and $R$-band fluxes after the first 800 s have a decay slope of $\sim 0.3-0.4$, similar to what is observed at the same time in the X-ray band. This suggests a common origin for the X-ray and optical emissions at these epochs.

On the other hand, detailed observations in the $R$ and $i'$ bands may suggest that the optical decay slope may be steeper between 300 and 800 s. This may indicate that we are detecting a decay from an early optical ‘bump’, that is, that at such early times we are observing the fading emission from a faint reverse shock, which propagates backwards into the ejecta while they are refreshed by the late central engine activity (Zhang, Kobayashi & Mészáros 2003). A possible rebrightening is observed in the $i'$ band only. The significance is low and a monotonic decay is not ruled out. On the other hand, it is worth to point out that a similar feature has been detected at larger significance in the brighter GRB 060206 (Monfardini et al. 2006b), in which case the $R$ and $i'$ light curves could not be fitted with identical functions. If real, the rebrightening in the $i'$ band may be due to a second reverse shock, possibly initiated by the collision of the 300 s of the X-ray flare into the external medium.

The X-ray light curve breaks steeply at 11.5 ks, while no apparent corresponding break is observed in the $i'$ and $R$ bands. A time break produced by the passage of the cooling frequency through the X-ray spectrum would certainly account for this, since in such a case the break would be monochromatic.

On the other hand, based on the spectral and temporal analysis, we find that this is not likely to be the case and the X-ray break is most probably due to the cessation of energy injection. In such a case, and if the optical and X-ray emissions were produced by the same mechanism, a break should be expected to appear in the optical emission, at $\sim t_{\text{break,2}}$. Here, we only note that observations are sparse at this time; there are no data in the $i'$ band measured after 5 ks and the only $R$-band measurement taken after 11.5 ks indicates that the light curve does not break. The fit of the optical light curve with a single power law suggests that an optical break may not be required even in correspondence of the first X-ray break. It is therefore possible that the GRB 060108 behaviour is similar to that of other GRBs, which do not present a break in the optical contemporaneous to that in the X-ray (see Panaiteescu et al. 2006). A satisfactory explanation for this behaviour is still lacking. Alternatively, if the $R$-band observation ($R = 23.5$ mag taken at 12.67 d after the trigger) is attributed to emission from the host galaxy of the GRB, a break in the optical GRB light curve at $t_{\text{break,2}}$ would not have been observed. As mentioned before, a significant host galaxy contamination is expected, since the source appears to be extended in the late VLT image.

4.2 Observed darkness

Fig. 7 shows the light curve of GRB 060108 in the broader context of other GRBs. One peculiar characteristic of this event is that, although the burst is detected in the $BVRi'$ bands at later times, the UVOT does not observe any optical/UV emission within the first $\sim 300$ s (i.e. during the tail of the prompt emission where internal shocks are expected to occur).

In order to investigate the possible reason for this behaviour, we can compare the relative faintness of GRB 060108 with other bursts using the X-ray flux versus gamma-ray fluence and the optical flux versus X-ray flux plots published by Roming et al. (2006).

In the case of GRB 060108, at 1 h after the burst the X-ray flux is $3.1 \times 10^{-12}$ erg cm$^{-2}$ s$^{-1}$ and the gamma-ray fluence is $\mathcal{F} = 4.9 \times 10^{-7}$ erg cm$^{-2}$, in the 2–10 and 15–350 keV bands, respectively. As we can see from the fig. 3 of Roming et al. (2006), this burst is not unusual and sits solidly within $2\sigma$ of the mean, although overall it is slightly fainter in both gamma- and X-rays compared to other GRBs. We therefore expect a typical behaviour also in the optical emission (perhaps with a slightly fainter optical afterglow than other bursts). If we compare the X-ray and optical fluxes at 1 h after the trigger (when the optical flux is $\sim 8.0$ $\mu$Jy), we find values within the range of the population with a slight X-ray to optical excess. Similarly, if we extrapolate the optical point at 11 h, we find an optical flux of $\sim3.9$ $\mu$Jy, while the X-ray flux is $4 \times 10^{-13}$ erg cm$^{-2}$ s$^{-1}$. Although we caution that the behaviour of the light curve at 11 h is not well constrained (see below), if taken face value this would imply that GRB 060108 still lies in the $2\sigma$ limit, near the region of optically faint events.

A further way to assess the ‘darkness’ of a GRB has been proposed by Jakobsson et al. (2004) (see also Rol et al. 2005), based on the optical to X-ray spectral properties. According to these authors, a burst can be classified as ‘truly’ dark when $\dot{\rho}_{\text{OX}} < 0.5$. A ratio less than this threshold would be in disagreement with the spectral slopes expected from the synchrotron emission, requiring an intrinsic ‘lack’ of optical emission. Indeed, the ratio of X-ray and $R$-band measurements of GRB 060108 provides a value of $\dot{\rho}_{\text{OX}} = 0.45$, as measured at $\sim 1000$ s after the burst trigger. According to the Jakobsson et al. (2004) classification, this burst is therefore ‘dark’ (see Fig. 8).

In principle, a possible explanation for the ‘observed darkness’ is a large redshift ($z > 5$, Lamb & Reichart 2000; Grenier et al. 2006; Kawai et al. 2006). In such a case, the UV light, which is heavily attenuated by intergalactic hydrogen, is redshifted into the optical band. The burst would then appear very red. However, the
5 CONCLUSIONS

We presented and discussed the gamma-ray, X-ray and UV/optical/IR observations of the *Swift* GRB 060108, performed with the instruments onboard the spacecraft as well as with the ground-based FTN, UKIRT and VLT. GRB 060108 has a moderately faint X-ray afterglow, but very low optical emission, making it one of the ‘darkest’ GRBs ever observed. We suggest that faintness of the optical emission may be due to an intrinsic weakness of the burst and a hard optical to X-ray spectrum, accompanied by some degree of extinction which occurred in the GRB surroundings.

The X-ray light curve shows the typical template discovered by *Swift*, characterized by a rapid decay in the first 300 s (commonly interpreted as the tail of the prompt emission based on the combined temporal/spectral properties) followed by a flat decay slope (typical of ‘refreshed’ afterglows). An X-ray flare is observed at ~300 s, although the statistic is low. The flat decay phase lasts for about ~10 ks, after that the light curve breaks into a steeper segment with a power-law decay index of 1.0, typical of a standard afterglow phase.

A comparison with the optical light curve is quite interesting. While the optical flux after 800 s has a slope of $\alpha = 0.4$, similar to that of the X-ray in the same interval, the decay index before this time is likely to be steeper. This behaviour may be explained if we interpret the fast decay as the reverse shock emission, while the later, flatter emission, has the same origin as the X-ray one. A possible rebrightening is visible only in the IR, although a monotonic decay is not ruled out. A similar feature has been seen in the case of GRB 060206 (Monardini et al. 2006b). If real, it might indicate a second reverse shock emission, initiated by the 300-s flare. Alternative models, able to explain an optical rebrightening, include either an increase in the density of the medium where the forward shock is produced (Lazzati et al. 2002), or energy injection by late shells (Björnsson, Gudmundsson & Jóhannesson 2004; Jóhannesson et al. 2006). This last scenario is less likely, because of our finding that the late energy injection is taking place at a steady rate. The coincidence of the rebrightening with the X-ray flare, however, favours the hypothesis of reverse shock.

Another intriguing feature of the optical light curve is the absence of a break in correspondence to the X-ray one at ~10 ks, which may be either intrinsic or due to a significant contribution to the optical flux at late times by the host galaxy. However, the poor sampling of the late optical light curve does not allow us to better constrain this behaviour.

The analysis of the optical spectrum, obtained from data gathered 45 min after the burst, has allowed us to determine an upper limit of $z < 3.2$ at 90 per cent confidence level, by using a $\chi^2$ minimization of the observed SED.

The optical afterglow is below the detection limit of the UVOT within 100 s of the burst. This event has shown how observations taken promptly and deeply enough may reveal the interesting behaviour of the early optical emission. In the *Swift* era, further similar observations are a reality due to the prompt response of both the spacecraft and ground-based robotic telescopes, as well as due to the possibility to perform deep observations with large telescopes at early times after the trigger.
